

Aneutronic Fusion with a Dense Plasma Focus Device Results and Plans

Lawrenceville Plasma Physics

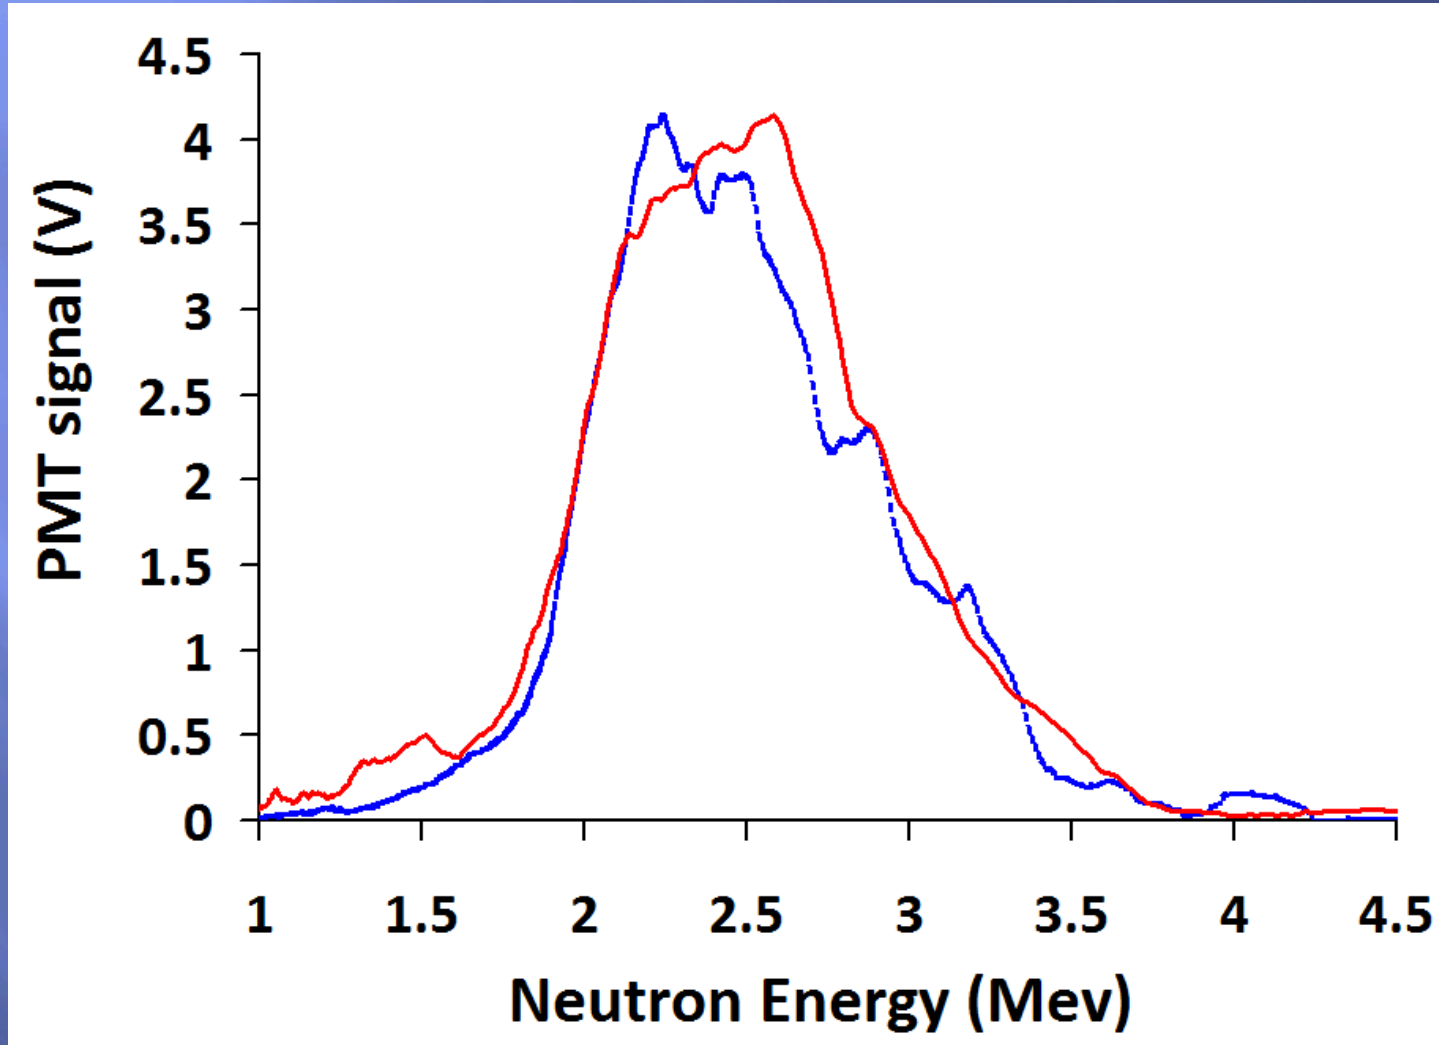

Focus-Fusion-1

8-Capacitor Configuration

Stored energy	43-60kJ
Capacitor potential	35-40 kV
Capacitance	75 μ F
Peak current	1.2 MA
Pressure	10-30 torr

**Key Feature: Small electrodes for MA DPF
(5 cm cathode, 2.8 cm anode)**

Ion energy of 160 keV

Low Anisotropy Rules Out Beam as Main Source of Neutrons

- ▣ 0 degree detector <0.3% of neutrons
- ▣ 12 degree <4.5% of neutron
- ▣ For unconfined beam-plasmoid expect anisotropy of 2.6, measure 1.25 so <23% of neutrons
- ▣ So >70% from confined ions

Duration & Density

- ▣ From neutron TOF, images: duration~ 10 ns
- ▣ 30 ion orbits, 200x Alfven time
- ▣ From 1.7×10^{11} neutron yield, volume:

Density $\sim 8 \times 10^{19}/\text{cc}$

Neutron calibration-thanks to PPPL

How do we get it so hot?

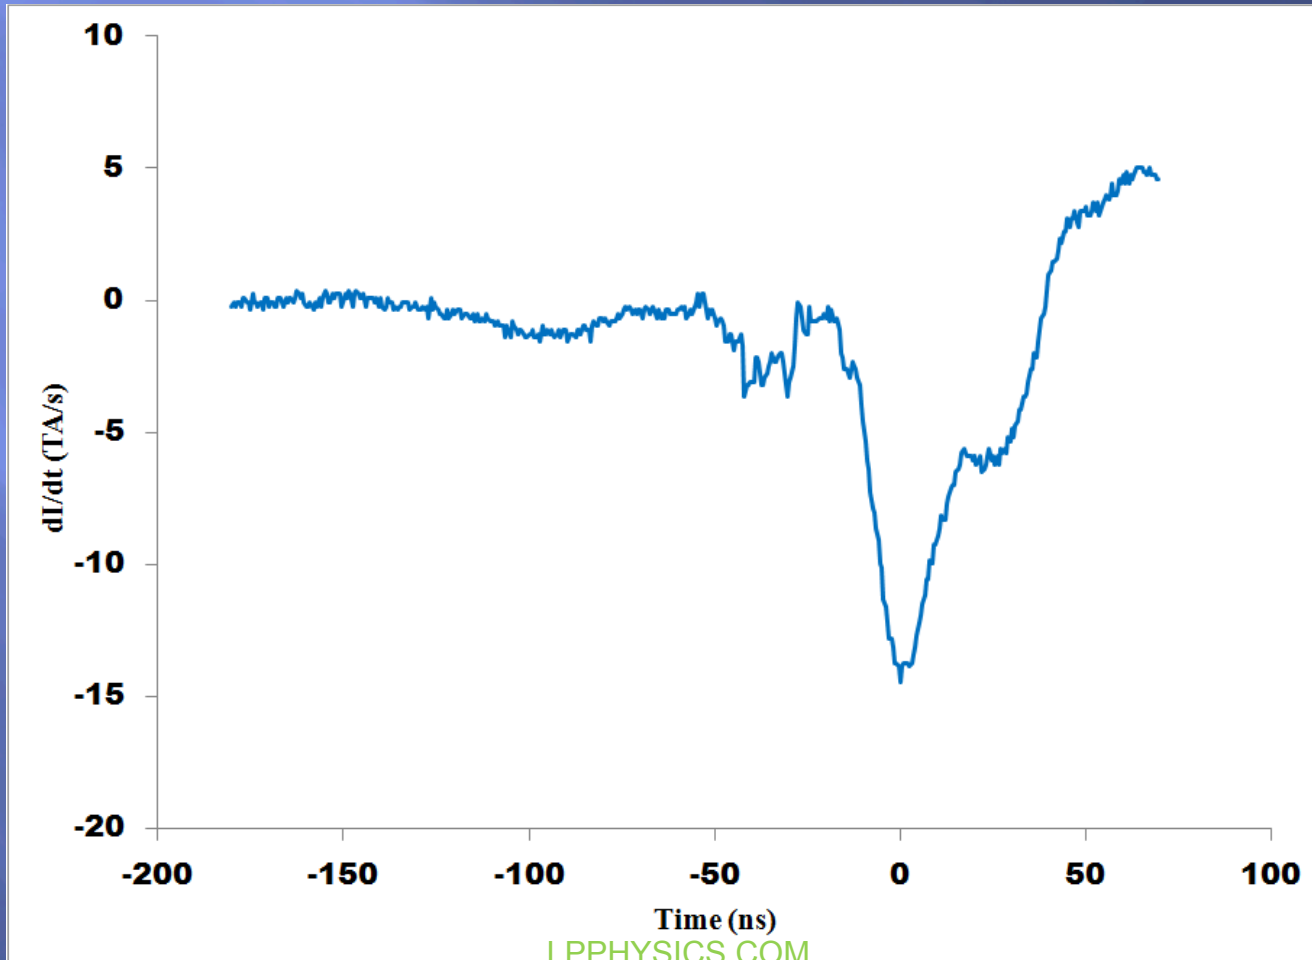

Viscous heating (Haines, Abolhasani) heats
plasmoid

Theory shows $T \sim B^{0.4}$

Our smaller electrode size leads to higher B

At higher currents, electron beam causes wave
heating as well

Hurdles to Higher Density: Early Beam

2kJ Ion Beam Is Emitted 30-50 ns before Pinch

Split
Sheath
Causes
Early
Beam

First sheath forms plasma jet— Sausage instability follows

Plasmoid,
8 ns after
pinch
200 micron
radius

What We Should See

W.H.Bostick : evolution of PF filaments

A

End of coaxial gun

B

Output of filaments axial

C

Output of filaments radial

D

Pinch phase axial

E

Pinch phase radial

F

Later filaments in halos

The Pinch Effect Revisited, *Int. Journ. Of Fusiopn Energy*, 1, 1977, 1-55

What we actually see

Filament Disruption by Arcing Leads to Split Sheath

Solution:

**Monolithic
W-Cu
cathode**

Path to Higher Density

- ▣ Preserve filaments to get theoretical density— $8 \times 10^{21}/\text{cc}$
- ▣ Increase current to 2.8 MA, shorten electrodes-- $4 \times 10^{22}/\text{cc}$
- ▣ Heavier gases, mixtures, pB11-- $10^{24}/\text{cc}$

Quantum Magnetic Field Effect

Angular momentum quantized,

Landau energy levels:

$$E_b = (n+1/2) ehB/mc = 11.6eVB(GG)$$

Since maximum momentum transfer is mv ,
where v is relative velocity, for $mv^2/2 < E_b$
very little excitation from ground level, very
little energy transfer.

$$E_i < (M/m) E_b$$

For $E_i = 300\text{keV}$,

$B > 14\text{GG}$ for p

$B > 3.5\text{GG}$ for a

$B > 1.3\text{GG}$ for ^{11}B

Quantum Magnetic Field Effect

New Idea:

QMFE acts only for ions moving parallel to B field—those moving perp to B will lose energy rapidly to electrons

Electrons act to “herd” ions in B direction

Ions preferentially moving along B field will have relative velocities enhanced by $3^{0.5}$

Thus effective T could be enhanced by 3

Summary

Results:

- ▣ 160 KeV confined >10 ns
- ▣ 10% energy transfer to plasmoid
- ▣ Density $8 \times 10^{19}/\text{cc}$

Plans:

- ▣ Eliminate impurities, preserve filaments with monolithic tungsten cathode
- ▣ Concerns—will tungsten take thermal stress?
